# On generalized computable universal priors and their  

Marcus Hutter<br>IDSIA, Galleria 2, CH-6928 Manno-Lugano, Switzerland

#### Abstract

Solomonoff unified Occam's razor and Epicurus' principle of multiple explanations to one elegant, formal, universal theory of inductive inference, which initiated the field of algorithmic information theory. His central result is that the posterior of the universal semimeasure $M$ converges rapidly to the true sequence generating posterior $\mu$, if the latter is computable. Hence, $M$ is eligible as a universal predictor in case of unknown $\mu$. The first part of the paper investigates the existence and convergence of computable universal (semi) measures for a hierarchy of computability classes: recursive, estimable, enumerable, and approximable. For instance, $M$ is known to be enumerable, but not estimable, and to dominate all enumerable semimeasures. We present proofs for discrete and continuous semimeasures. The second part investigates more closely the types of convergence, possibly implied by universality: in difference and in ratio, with probability 1 , in mean sum, and for Martin-Löf random sequences. We introduce a generalized concept of randomness for individual sequences and use it to exhibit difficulties regarding these issues. In particular, we show that convergence fails (holds) on generalized-random sequences in gappy (dense) Bernoulli classes.

## 1. Introduction

All induction problems can be phrased as sequence prediction tasks. This is, for instance, obvious for time-series prediction, but also includes classification tasks. Having observed data $x_{t}$ at times $t<n$, the task is to predict the $t$ th symbol $x_{t}$ from sequence $x=x_{1} \ldots x_{t-1}$. The key concept to attack general induction problems is Occam's razor (simplicity) principle, which says that "Entities should not be multiplied beyond necessity." and to a less extent Epicurus' principle of multiple explanations. The former/latter may be interpreted as to keep the simplest/all theories consistent with the observations $x_{1} \ldots x_{t-1}$ and to use these theories to predict $x_{t}$. Kolmogorov (and others) defined the complexity of a string as the length of its shortest description on a universal Turing machine. The Kolmogorov complexity $K$ is an excellent universal complexity measure, suitable for quantifying Occam's razor. There is (only) one disadvantage: $K$ is not computable.

[^0]More precisely, a function $f$ is said to be recursive (or finitely computable) if there exists a Turing machine that, given $x$, computes $f(x)$ and then halts. Some functions are not recursive but still approximable (or limit-computable) in the sense that there is a non-halting Turing machine with an infinite ( $x$-dependent) output sequence $y_{1}, y_{2}, y_{3}, \ldots$ and $\lim _{t \rightarrow \infty} y_{t}=f(x)$. If additionally the output sequence is monotone increasing/decreasing, then $f$ is said to be lower/upper semicomputable (or enumerable/co-enumerable). Finally, we call $f$ estimable if some Turing machine, given $x$ and a precision $\varepsilon$, finitely computes an $\varepsilon$-approximation of $x$. The major algorithmic property of $K$ is that it is co-enumerable, but not recursive.

More suitable for predictions is Solomonoff's $[18,19]$ universal prior $M(x)$ defined as the probability that the output of a universal monotone Turing machine $U$ starts with string $x$ when provided with fair coin flips on the input tape. $M(x)$ is enumerable and roughly $2^{-K(x)}$, hence implementing Occam's and also Epicurus' principles.
Assume now that strings $x$ are sampled from a probability distribution $\mu$, i.e. the probability of a string starting with $x$ shall be $\mu(x)$. The probability of observing $x_{t}$ at time $t$, given past observations $x_{1} \ldots x_{t-1}$ is $\mu\left(x_{t} \mid x_{1} \ldots x_{t-1}\right)=$ $\mu\left(x_{1} \ldots x_{t}\right) / \mu\left(x_{1} \ldots x_{t-1}\right)$. Solomonoff's [19] central result is that the universal posterior $M\left(x_{t} \mid x_{1} \ldots x_{t-1}\right)=$ $M\left(x_{1} \ldots x_{t}\right) / M\left(x_{1} \ldots x_{t-1}\right)$ converges rapidly to the true (objective) posterior probability $\mu\left(x_{t} \mid x_{1} \ldots x_{t-1}\right)$, if $\mu$ is an estimable measure, hence $M$ can be used for predictions in case of unknown $\mu$. One representation of $M$ is as a $2^{-K(\mu)}$-weighted sum of all enumerable "defective" probability measures, called semimeasures. The (from this representation obvious) dominance $M(x) \geqslant 2^{-K(\mu)} \mu(x)$ for all enumerable $\mu$ is the central ingredient in the convergence proof.
Dominance and convergence immediately generalize to arbitrary weighted sums of (semi)measures of some arbitrary countable set $\mathcal{M}$. So what is so special about the class of all enumerable semimeasures $\mathcal{M}_{\text {enum }}^{\text {semi }}$ ? The larger we choose $\mathcal{M}$ the less restrictive is the essential assumption that $\mathcal{M}$ should contain the true distribution $\mu$. Why not restrict to the still rather general class of estimable or recursive (semi)measures? For every countable class $\mathcal{M}$ and $\xi_{\mathcal{M}}(x):=$ $\sum_{v \in \mathcal{M}} w_{v} v(x)$ with $w_{v}>0$, the important dominance $\xi_{\mathcal{M}}(x) \geqslant w_{v} v(x) \forall v \in \mathcal{M}$ is satisfied. The question is what properties $\xi_{\mathcal{M}}$ possesses. The distinguishing property of $\mathcal{M}_{\text {enum }}^{\text {semi }}$ is that $M=\xi_{\mathcal{M}}$ semim is itself an element of $\mathcal{M}_{\text {enum }}^{\text {semi }}$. On the other hand, for prediction, $\xi_{\mathcal{M}} \in \mathcal{M}$ is not by itself an important property. What matters is whether $\xi_{\mathcal{M}}$ is computable (in one of the senses we defined above) to avoid getting into the (un)realm of non-constructive math.
Our first contribution is to classify the existence of generalized computable (semi)measures. From [23] we know that there is an enumerable semimeasure (namely $M$ ) that dominates all enumerable semimeasures in $\mathcal{M}_{\text {enum }}^{\text {semi }}$. We show that there is no estimable semimeasure that dominates all computable measures (also mentioned in [23]), and there is no approximable semimeasure that dominates all approximable measures. From this it follows that for a universal (semi)measure that at least satisfies the weakest form of computability, namely being approximable, the largest dominated class among the classes considered in this work is the class of enumerable semimeasures. This is the distinguishing property of $\mathcal{M}_{\text {enum }}^{\text {semi }}$ and $M$. This investigation was motivated by recent generalizations of Kolmogorov complexity and Solomonoff's prior by Schmidhuber [14,15].
The second contribution is to investigate more closely the types of convergence, possibly implied by universality: in difference and in ratio, with probability 1 , in mean sum, and for Martin-Löf (M.L.) random sequences. We introduce a generalized concept of randomness for individual sequences and use it to exhibit difficulties regarding these issues. More concretely, we consider countable classes $\mathcal{M}$ of Bernoulli environments and show that $\xi_{\mathcal{M}}$ converges to $\mu$ on all generalized-random sequences if and only if the class is dense.

Contents: In Section 2, we review various computability concepts and discuss their relation. In Section 3, we define the prefix Kolmogorov complexity $K$, the concept of (semi)measures, Solomonoff's universal prior $M$, and explain its universality. Section 4 summarizes Solomonoff's major convergence result, discusses general mixture distributions and the important universality property-multiplicative dominance. In Section 5, we define seven classes of (semi)measures based on four computability concepts. Each class may or may not contain a (semi)measures that dominates all elements of another class. We reduce the analysis of these 49 cases to four basic cases. Domination (essentially by $M$ ) is known to be true for two cases. The other two cases do not allow for domination. In Section 7, we investigate more closely the type of convergence implied by universality. We summarize the result on posterior convergence in difference ( $\xi-\mu \rightarrow 0$ ) and improve the previous result [13] on the convergence in ratio $\xi / \mu \rightarrow 1$ by showing rapid convergence without use of martingales. In Section 8, we investigate whether convergence for all M.L. random sequences could hold. We define a generalized concept of randomness for individual sequences and use it to show that proofs based on universality cannot decide this question. Section 9 concludes the paper.

Notation: We denote strings of length $n$ over finite alphabet $\mathcal{X}$ by $x=x_{1} x_{2} \ldots x_{n}$ with $x_{t} \in \mathcal{X}$ and further abbreviate $x_{1: n}:=x_{1} x_{2} \ldots x_{n-1} x_{n}$ and $x_{<n}:=x_{1} \ldots x_{n-1}, \varepsilon$ for the empty string, $\ell(x)$ for the length of string $x$, and $\omega=x_{1: \infty}$ for infinite sequences. We write $x y$ for the concatenation of string $x$ with $y$. We abbreviate $\lim _{n \rightarrow \infty}[f(n)-g(n)]=0$ by $f(n) \xrightarrow{n \rightarrow \infty} g(n)$ and say $f$ converges to $g$, without implying that $\lim _{n \rightarrow \infty} g(n)$ itself exists. We write $f(x) \unrhd g(x)$ for $g(x)=\mathrm{O}(f(x))$, i.e. if $\exists c>0: f(x) \geqslant c g(x) \forall x$.

## 2. Computability concepts

We define several computability concepts weaker than can be captured by halting Turing machines.
Definition 1 (Computable functions). We consider functions $f: \mathbb{N} \rightarrow \mathbb{R}$ :
$f$ is recursive or finitely computable iff there are Turing machines $T_{1 / 2}$ with output interpreted as natural numbers and $f(x)=\frac{T_{1}(x)}{T_{2}(x)}$.
$f$ is approximable or limit-computable iff $\exists$ recursive $\phi(\cdot, \cdot)$ with $\lim _{t \rightarrow \infty} \phi(x, t)=f(x)$.
$f$ is enumerable or lower semicomputable iff additionally $\phi(x, t) \leqslant \phi(x, t+1)$.
$f$ is co-enumerable or upper semicomputable iff $[-f]$ is lower semicomputable.
$f$ is semicomputable iff $f$ is lower- or upper semicomputable.
$f$ is estimable iff $f$ is lower- and upper semicomputable.
If $f$ is estimable we can finitely compute an $\varepsilon$-approximation of $f$ by upper and lower semicomputing $f$ and terminating when differing by less than $\varepsilon$. This means that there is a Turing machine which, given $x$ and $\varepsilon$, finitely computes $\hat{y} \in \mathbb{Q}$ such that $|\hat{y}-f(x)|<\varepsilon$. Moreover, it gives an interval estimate $f(x) \in[\hat{y}-\varepsilon, \hat{y}+\varepsilon]$. An estimable integer-valued function is recursive (take any $\varepsilon<\frac{1}{2}$ ). Note that if $f$ is only approximable or semicomputable we can still come arbitrarily close to $f(x)$ but we cannot devise a terminating algorithm that produces an $\varepsilon$-approximation. In the case of lower/upper semicomputability we can at least finitely compute lower/upper bounds to $f(x)$. In case of approximability, the weakest computability form, even this capability is lost.

What we call estimable/recursive/finitely computable is often just called computable, but it makes sense to separate the concepts in this work, since finite computability is conceptually easier and some previous results have only been proved for this case. Sometimes we use the word computable generically for some of the computability forms of Definition 1.

## 3. The universal prior $M$

The prefix Kolmogorov complexity $K(x)$ is defined as the length of the shortest binary (prefix) program $p \in\{0,1\}^{*}$ for which a universal prefix Turing machine $U$ (with binary program tape and $\mathcal{X}$ ary output tape) outputs string $x \in \mathcal{X}^{*}$, and similarly $K(x \mid y)$ in case of side information $y[9,12,3,1]$ :

$$
K(x)=\min \{\ell(p): U(p)=x\}, \quad K(x \mid y)=\min \{\ell(p): U(p, y)=x\} .
$$

Solomonoff [18, Eq. (7)] defined (earlier) the closely related quantity, the universal posterior $M(y \mid x)=M(x y) / M(x)$. The universal prior $M(x)$ can be defined as the probability that the output of a universal monotone Turing machine $U$
starts with $x$ when provided with fair coin flips on the input tape. Formally, $M$ can be defined as

$$
\begin{equation*}
M(x):=\sum_{p: U(p)=x *} 2^{-\ell(p)} \tag{1}
\end{equation*}
$$

where the sum is over minimal programs $p$ for which $U$ outputs a string starting with $x$. The so-called minimal programs are defined similarly to the prefix programs, but $U$ need not halt, which is indicated by the $*$. Minimal programs are those which are left to the input head in the moment when $U$ wrote the last bit of $x[13,7]$. Before we can discuss the stochastic properties of $M$ we need the concept of (semi)measures for strings.

Definition 2 (Continuous (Semi)measures). $\mu(x)$ denotes the probability that a sequence starts with string $x$. We call $\mu \geqslant 0$ a (continuous) semimeasure if $\mu(\varepsilon) \leqslant 1$ and $\mu(x) \geqslant \sum_{a \in \mathcal{X}} \mu(x a)$, and a (probability) measure if equalities hold.

The reason for calling $\mu$ with the above property a probability measure is that it satisfies Kolmogorov's axioms of probability in the following sense: the sample space is $\mathcal{X}^{\infty}$ with elements $\omega=\omega_{1} \omega_{2} \omega_{3} \ldots \in \mathcal{X}^{\infty}$ being infinite sequences over alphabet $\mathcal{X}$. The set of events (the $\sigma$-algebra) is defined as the set generated from the cylinder sets $\Gamma_{x_{1: n}}:=\left\{\omega: \omega_{1: n}=x_{1: n}\right\}$ by countable union and complement. A probability measure $\mu$ is uniquely defined by giving its values $\mu\left(\Gamma_{x_{1: n}}\right)$ on the cylinder sets, which we abbreviate by $\mu\left(x_{1: n}\right)$. We will also call $\mu$ a measure, or even more loose a probability distribution.

We have $\sum_{a \in \mathcal{X}} M(x a)<M(x)$ because there are programs $p$ that output $x$, not followed by any $a \in \mathcal{X}$. They just stop after printing $x$ or continue forever without any further output. Together with $M(\varepsilon)=1$ this shows that $M$ is a semimeasure, but not a probability measure. We can now state the fundamental property of $M$ [23,19]:

Theorem 3 (Universality of $M$ ). The universal prior $M$ is an enumerable semimeasure that multiplicatively dominates all enumerable semimeasures in the sense that $M(x) \unrhd 2^{-K(\rho)} \cdot \rho(x)$ for all enumerable semimeasures $\rho . M$ is enumerable, but not estimable (nor recursive).

The Kolmogorov complexity of a function like $\rho$ is defined as the length of the shortest self-delimiting code of a Turing machine computing this function in the sense of Definition 1 . Up to a multiplicative constant, $M$ assigns higher probability to all $x$ than any other computable probability distribution.

It is possible to normalize $M$ to a true probability measure $M_{\text {norm }}[19,13]$ with dominance still being true, but at the expense of giving up enumerability ( $M_{\text {norm }}$ is still approximable). $M$ is more convenient when studying algorithmic questions, but a true probability measure like $M_{\text {norm }}$ is more convenient when studying stochastic questions.

## 4. Universal sequence prediction

In which sense does $M$ incorporate Occam's razor and Epicurus' principle of multiple explanations? Since the shortest programs $p$ dominate the sum in $M, M(x)$ is roughly equal to $2^{-K(x)}\left(M(x)=2^{-K(x)+\mathrm{O}(K(\ell(x))}\right)$, i.e. $M$ assigns high probability to simple strings. More useful is to think of $x$ as being the observed history. We see from (1) that every program $p$ consistent with history $x$ is allowed to contribute to $M$ (Epicurus). On the other hand, shorter programs give significantly larger contribution (Occam). How does all this affect prediction? If $M(x)$ describes our (subjective) prior belief in $x$, then $M(y \mid x):=M(x y) / M(x)$ must be our posterior belief in $y$. From the symmetry of algorithmic information $K(x y) \approx K(y \mid x)+K(x)$, and $M(x) \approx 2^{-K(x)}$ and $M(x y) \approx 2^{-K(x y)}$ we get $M(y \mid x) \approx 2^{-K(y \mid x)}$. This tells us that $M$ predicts $y$ with high probability iff $y$ has an easy explanation, given $x$ (Occam and Epicurus).

The above qualitative discussion should not create the impression that $M(x)$ and $2^{-K(x)}$ always lead to predictors of comparable quality. Indeed, in the online/incremental setting, $K(y)=\mathrm{O}(1)$ invalidates the consideration above. The proof of (3), for instance, depends on $M$ being a semimeasure and the chain rule being exactly true, neither of them is satisfied by $2^{-K(x)}$. See [6] for a detailed analysis.

Sequence prediction algorithms try to predict the continuation $x_{t} \in \mathcal{X}$ of a given sequence $x_{1} \ldots x_{t-1}$. The following bound shows that $M$ predicts computable sequences well:

$$
\begin{equation*}
\sum_{t=1}^{\infty}\left(1-M\left(x_{t} \mid x_{<t}\right)\right)^{2} \leqslant-\frac{1}{2} \sum_{t=1}^{\infty} \ln M\left(x_{t} \mid x_{<t}\right)=-\frac{1}{2} \ln M\left(x_{1: \infty}\right) \leqslant \frac{1}{2} \ln 2 \cdot K m\left(x_{1: \infty}\right) \tag{2}
\end{equation*}
$$

where the monotone complexity $\operatorname{Km}\left(x_{1: \infty}\right)=\min \left\{\ell(p): U(p)=x_{1: \infty}\right\}$ is defined as the length of the shortest (non-halting) program computing $x_{1: \infty}[23,11]$. In the first inequality we have used $(1-a)^{2} \leqslant-\frac{1}{2} \ln a$ for $0 \leqslant a \leqslant 1$. In the equality we exchanged the sum with the logarithm and eliminated the resulting product by the chain rule. In the last inequality we used $M(x) \geqslant 2^{-K m(x)}$, which follows from (1) by dropping all terms in $\sum_{p}$ except for the shortest $p$ computing $x$. If $x_{1: \infty}$ is a computable sequence, then $\operatorname{Km}\left(x_{1: \infty}\right)$ is finite, which implies $M\left(x_{t} \mid x_{<t}\right) \rightarrow 1$ ( $\sum_{t=1}^{\infty}\left(1-a_{t}\right)^{2}<\infty \Rightarrow a_{t} \rightarrow 1$ ). This means, that if the environment is a computable sequence (which so ever, e.g. the digits of $\pi$ or $e$ in $\mathcal{X}$ ary representation), after having seen the first few digits, $M$ correctly predicts the next digit with high probability, i.e. it recognizes the structure of the sequence.

Assume now that the true sequence is drawn from a computable probability distribution $\mu$, i.e. the true (objective) probability of $x_{1: t}$ is $\mu\left(x_{1: t}\right)$. The probability of $x_{t}$ given $x_{<t}$ hence is $\mu\left(x_{t} \mid x_{<t}\right)=\mu\left(x_{1: t}\right) / \mu\left(x_{<t}\right)$. Solomonoff's [19] central result is that $M$ converges to $\mu$. More precisely, for binary alphabet, he showed that

$$
\begin{equation*}
\sum_{t=1}^{\infty} \sum_{x_{<t} \in\{0,1\}^{t-1}} \mu\left(x_{<t}\right)\left(M\left(0 \mid x_{<t}\right)-\mu\left(0 \mid x_{<t}\right)\right)^{2} \leqslant \frac{1}{2} \ln 2 \cdot K(\mu)+\mathrm{O}(1)<\infty . \tag{3}
\end{equation*}
$$

The infinite sum can only be finite if the difference $M\left(0 \mid x_{<t}\right)-\mu\left(0 \mid x_{<t}\right)$ tends to zero for $t \rightarrow \infty$ with $\mu$-probability 1 (see Definition 9 (i) and [4] or Section 7 for general alphabet). This holds for any computable probability distribution $\mu$. The reason for the astonishing property of a single (universal) function to converge to any computable probability distribution lies in the fact that the set of $\mu$-random sequences differ for different $\mu$. Past data $x_{<t}$ are exploited to get a (with $t \rightarrow \infty$ ) improving estimate $M\left(x_{t} \mid x_{<t}\right)$ of $\mu\left(x_{t} \mid x_{<t}\right)$.

The universality property (Theorem 3) is the central ingredient in the proof of (3). The proof involves the construction of a semimeasure $\xi$ whose dominance is obvious. The hard part is to show its enumerability and equivalence to $M$. Let $\mathcal{M}$ be the (countable) set of all enumerable semimeasures and define

$$
\begin{equation*}
\xi(x):=\sum_{v \in \mathcal{M}} 2^{-K(v)} v(x) . \tag{4}
\end{equation*}
$$

Then dominance

$$
\begin{equation*}
\xi(x) \geqslant 2^{-K(v)} v(x) \quad \forall v \in \mathcal{M} \tag{5}
\end{equation*}
$$

is obvious. Is $\xi$ lower semicomputable? To answer this question one has to be more precise. Levin [23] has shown that the set of all lower semicomputable semimeasures is enumerable (with repetitions). For this (ordered multi) set $\mathcal{M}=\mathcal{M}_{\text {enum }}^{\text {semi }}:=\left\{v_{1}, v_{2}, v_{3}, \ldots\right\}$ and $K\left(v_{i}\right):=K(i)$ one can easily see that $\xi$ is lower semicomputable. Finally, proving $M(x) \unrhd \xi(x)$ also establishes universality of $M$ (see [19,13] for details).

The advantage of $\xi$ over $M$ is that it immediately generalizes to arbitrary weighted sums of (semi)measures for arbitrary countable $\mathcal{M}$.

## 5. Universal (semi)measures

What is so special about the set of all enumerable semimeasures $\mathcal{M}_{\text {enum }}^{\text {semi }}$ ? The larger we choose $\mathcal{M}$ the less restrictive is the assumption that $\mathcal{M}$ should contain the true distribution $\mu$, which will be essential throughout the paper. Why do we not restrict to the still rather general class of estimable or recursive (semi)measures? It is clear that for every countable (multi)set $\mathcal{M}$, the universal or mixture distribution

$$
\begin{equation*}
\xi(x):=\xi_{\mathcal{M}}(x):=\sum_{v \in \mathcal{M}} w_{\nu} v(x) \quad \text { with } \sum_{v \in \mathcal{M}} w_{v} \leqslant 1 \quad \text { and } \quad w_{v}>0 \tag{6}
\end{equation*}
$$

dominates all $v \in \mathcal{M}$. This dominance is sufficient for the desired convergence $\xi \rightarrow \mu$ similarly to (3). The question is what properties $\xi$ possesses. The distinguishing property of $\mathcal{M}_{\text {enum }}^{\text {semi }}$ is that $\xi$ is itself an element of $\mathcal{M}_{\text {enum }}^{\text {semi }}$. When concerned with predictions, $\xi_{\mathcal{M}} \in \mathcal{M}$ is not by itself an important property, but whether $\xi$ is computable in one of the senses of Definition 1. We define
$\mathcal{M}_{1} \unrhd \mathcal{M}_{2}: \Leftrightarrow$ there is an element of $\mathcal{M}_{1}$ that dominates all elements of $\mathcal{M}_{2}$

$$
: \Leftrightarrow \exists \rho \in \mathcal{M}_{1} \forall v \in \mathcal{M}_{2} \exists w_{v}>0 \forall x: \rho(x) \geqslant w_{v} v(x) .
$$

Table 1

| $r$ | appr. | $y e s^{i i}$ | $y e s^{i i}$ | yes ${ }^{\text {ii }}$ | $n o^{i v}$ | yes ${ }^{\text {ii }}$ | yes ${ }^{\text {ii }}$ | $n o^{i v}$ |

The entry in row $r$ and column $c$ indicates whether there is an $r$-able (semi)measure $\rho$ dominating the set $\mathcal{M}$ that contains all $c$-able (semi)measures, where $r, c \in\{$ recurs, estimat, enumer, approxim\}. Enumerable measures are estimable. This is the reason why the enum. row and column in case of measures are missing. The superscript indicates from which part of Theorem 4 the answer follows. For the bold face entries directly, for the others using transitivity of $\unrhd$.
$\unrhd$ is transitive (but not necessarily reflexive) in the sense that $\mathcal{M}_{1} \unrhd \mathcal{M}_{2} \unrhd \mathcal{M}_{3}$ implies $\mathcal{M}_{1} \unrhd \mathcal{M}_{3}$ and $\mathcal{M}_{0} \supseteq$ $\mathcal{M}_{1} \unrhd \mathcal{M}_{2} \supseteq \mathcal{M}_{3}$ implies $\mathcal{M}_{0} \unrhd \mathcal{M}_{3}$. For the computability concepts introduced in Section 2, we have the following proper set inclusions:

where $\mathcal{M}_{c}^{\text {msr }}$ stands for the set of all probability measures of appropriate computability type $c \in\{$ rec $=$ recursive, est $=$ estimable, enum $=$ enumerable, appr $=$ approximable $\}$, and similarly for semimeasures $\mathcal{M}_{c}^{\text {semi }}$. From an enumeration of a measure $\rho$ one can construct a co-enumeration by exploiting $\rho\left(x_{1: n}\right)=1-\sum_{y_{1: n} \neq x_{1: n}} \rho\left(y_{1: n}\right)$. This shows that every enumerable measure is also co-enumerable, hence estimable, which proves the identity $\equiv$ above.
With this notation, Theorem 3 implies $\mathcal{M}_{\text {enum }}^{\text {semi }} \unrhd \mathcal{M}_{\text {enum }}^{\text {semi }}$. Transitivity allows to conclude, for instance, that $\mathcal{M}_{\text {appr }}^{\text {semi }} \unrhd$ $\mathcal{M}_{\text {rec }}^{\mathrm{msr}}$, i.e. that there is an approximable semimeasure that dominates all recursive measures.
The standard "diagonalization" way of proving $\mathcal{M}_{1} \unrhd \mathcal{M}_{2}$ is to take an arbitrary $\mu \in \mathcal{M}_{1}$ and "increase" it to $\rho$ such that $\mu \unrhd \rho$ and show that $\rho \in \mathcal{M}_{2}$. There are $7 \times 7$ combinations of (semi)measures $\mathcal{M}_{1}$ with $\mathcal{M}_{2}$ for which $\mathcal{M}_{1} \unrhd \mathcal{M}_{2}$ could be true or false. There are four basic cases, explicated in the following theorem, from which the other 49 combinations displayed in Table 1 follow by transitivity.

Theorem 4 (Universal (semi)measures). A semimeasure $\rho$ is said to be universal for $\mathcal{M}$ if it multiplicatively dominates all elements of $\mathcal{M}$ in the sense $\forall v \exists w_{v}>0: \rho(x) \geqslant w_{v} v(x) \forall x$. The following holds true:
(o) $\exists \rho:\{\rho\} \unrhd \mathcal{M}$ : For every countable set of (semi)measures $\mathcal{M}$, there is a (semi)measure that dominates all elements of $\mathcal{M}$.
(i) $\mathcal{M}_{\text {enum }}^{\text {semi }} \unrhd \mathcal{M}_{\text {enum }}^{\text {semi }}$ : The class of enumerable semimeasures contains $a$ universal element.
(ii) $\mathcal{M}_{\mathrm{appr}}^{\mathrm{msr}} \unrhd \mathcal{M}_{\text {enum }}^{\text {semi }}$ : There is an approximable measure that dominates all enumerable semimeasures.
(iii) $\mathcal{M}_{\text {est }}^{\text {semi }} \unrhd \mathcal{M}_{\text {rec }}^{\mathrm{msr}}$ : There is no estimable semimeasure that dominates all recursive measures.
(iv) $\mathcal{M}_{\mathrm{appr}}^{\text {semi }} \notin \mathcal{M}_{\mathrm{appr}}^{\mathrm{msr}}$ : There is no approximable semimeasure that dominates all approximable measures.

If we ask for a universal (semi)measure that at least satisfies the weakest form of computability, namely being approximable, we see that the largest dominated set among the 7 sets defined above is the set of enumerable semimeasures. This is the reason why $\mathcal{M}_{\text {enum }}^{\text {semi }}$ plays a special role. On the other hand, $\mathcal{M}_{\text {enum }}^{\text {semi }}$ is not the largest set dominated by an approximable semimeasure, and indeed no such largest set exists. One may, hence, ask for "natural" larger sets $\mathcal{M}$. One such set, namely the set of cumulatively enumerable semimeasures $\mathcal{M}_{\text {CEM }}$, has recently been discovered by Schmidhuber [14,15], for which even $\xi_{\text {CEM }} \in \mathcal{M}_{\text {CEM }}$ holds.

Theorem 4 also holds for discrete (semi)measures $P$ defined as follows:
Definition 5 (Discrete (semi)measures). $P(x)$ denotes the probability of $x \in \mathbb{N}$. We call $P: \mathbb{N} \rightarrow[0,1]$ a discrete (semi)measure if $\sum_{x \in \mathbb{N}} P(x) \stackrel{(<)}{=} 1$.

Theorem 4 (i) is Levin's major result [13, Thm. 4.3.1, Thm. 4.5.1], and (ii) is due to Solomonoff [19]. The proof of $\mathcal{M}_{\mathrm{rec}}^{\text {semi }} \unrhd \mathcal{M}_{\mathrm{rec}}^{\text {semi }}$ in [13, p. 249] contains minor errors and is not extensible to (iii), and the proof in [13, p. 276] only applies to infinite alphabet and not to the binary/finite case considered here. $\mathcal{M}_{\text {est }}^{\text {semi }} \unrhd \mathcal{M}_{\text {est }}^{\text {semi }}$ is mentioned in [23] without proof. A direct proof of (iv) can be found in [7]. Here, we reduce (iv) to (iii) by exploiting the following elementary fact (well-known for integer-valued functions, see e.g. [17, p. 634]):

Lemma 6 (Approximable $=H$-estimable). A function is approximable iff it is estimable with the help of the halting oracle.

Proof. With $H$-computable we mean, computable with the help of the halting oracle, or equivalently, computable under extra input of the halting sequence $h=h_{1: \infty} \in\{0,1\}^{\infty}$, where $h_{n}=1: \Leftrightarrow U(n)$ halts.

Assume $f$ is approximable, i.e. $\forall \varepsilon \exists y, m: R(m, y, \varepsilon)$, where relation $R(m, y, \varepsilon):=\left[\forall n \geqslant m:\left|f_{n}(x)-y\right|<\varepsilon\right]$ and recursive $f_{n} \rightarrow f$. Fix $\varepsilon>0$. Search (dovetail) for $m \in \mathbb{N}$ and $y\left(\in \frac{1}{2} \varepsilon \mathbb{Z}\right.$ is sufficient) such that $R(m, y, \varepsilon)=$ true. $R$ is co-enumerable, hence $H$-decidable, hence $y$ can be $H$-computed, hence $f$ is $H$-estimable, since $f(x)=y \pm \mathrm{O}(\varepsilon)$.

Now assume that $f$ is $H$-estimable, i.e. $\exists T \in \mathrm{TM} \forall \varepsilon, x:|T(x, \varepsilon, h)-f(x)|<\varepsilon$. Since $h$ is enumerable, $T$ and hence $f$ are approximable. More formally, let $h_{n}^{t}=1: \Leftrightarrow U(n)$ halts within $t$ steps. Then $g(x, \varepsilon):=T(x, \varepsilon, h)=$ $T\left(x, \varepsilon, \lim _{t \rightarrow \infty} h^{t}\right)=\lim _{t \rightarrow \infty} T\left(x, \varepsilon, h^{t}\right)$ is approximable, where the exchange of limits holds, since $T$ only reads $n_{x \varepsilon}<\infty$ bits of $h$ and $h_{1: n_{x \varepsilon}}=h_{1: n_{x \varepsilon}}^{t}$ for sufficiently large $t$.

## 6. Proof of Theorem 4

We first prove the theorem for discrete (semi)measures $P$ (Definition 5), since it contains the essential ideas in a cleaner form. We then present the proof for continuous (semi)measures $\mu$ (Definition 2). We present proofs for binary alphabet $\mathcal{X}=\{0,1\}$ only. The proofs naturally generalize from binary to arbitrary finite alphabet. arg $\min _{x} f(x)$ is the $x$ that minimizes $f(x)$. Ties are broken in an arbitrary but computable way (e.g. by taking the smallest $x$ ).

## Proof (discrete case).

(o) $Q(x):=\sum_{P \in \mathcal{M}} w_{P} P(x)$ with $w_{P}>0$ obviously dominates all $P \in \mathcal{M}$ (with constant $w_{P}$ ). With $\sum_{P} w_{P}=1$ and all $P$ being discrete (semi)measures also $Q$ is a discrete (semi)measure.
(i) See [13, Thm. 4.3.1].
(ii) Let $P$ be the universal element in $\mathcal{M}_{\text {enum }}^{\text {semi }}$ and $\alpha:=\sum_{x} P(x)$. We normalize $P$ by $Q(x):=\frac{1}{\alpha} P(x)$. Since $\alpha \leqslant 1$ we have $Q(x) \geqslant P(x)$. Hence $Q \geqslant P \unrhd \mathcal{M}_{\text {enum }}^{\text {semi }}$. As a ratio between two enumerable functions, $Q$ is still approximable, hence $\mathcal{M}_{\text {appr }}^{\mathrm{msr}} \unrhd \mathcal{M}_{\text {enum }}^{\text {semi }}$.
(iii) Let $P \in \mathcal{M}_{\text {rec }}^{\text {semi }}$. We partition $\mathbb{N}$ into chunks $I_{n}:=\left\{2^{n-1}, \ldots, 2^{n}-1\right\}(n \geqslant 1)$ of increasing size. With $x_{n}:=$ $\arg \min _{x \in I_{n}} P(x)$ we define $Q\left(x_{n}\right):=\frac{1}{n(n+1)} \forall n$ and $Q(x):=0$ for all other $x$. Exploiting that a minimum is smaller than an average and that $\mu$ is a semimeasure, we get

$$
P\left(x_{n}\right)=\min _{x \in I_{n}} P(x) \leqslant \frac{1}{\left|I_{n}\right|} \sum_{x \in I_{n}} P(x) \leqslant \frac{1}{\left|I_{n}\right|}=\frac{1}{2^{n-1}}=\frac{n(n+1)}{2^{n-1}} Q\left(x_{n}\right) .
$$

Since $\frac{n(n+1)}{2^{n-1}} \rightarrow 0$ for $n \rightarrow \infty, P$ cannot dominate $Q(P \unrhd Q)$. With $P$ also $Q$ is recursive. Since $P$ was an arbitrary recursive semimeasure and $Q$ is a recursive measure $\left(\sum Q(x)=\sum\left[\frac{1}{n(n+1)}\right]=\sum\left[\frac{1}{n}-\frac{1}{n+1}\right]=1\right)$ this implies $\mathcal{M}_{\text {rec }}^{\text {semi }} \unrhd \mathcal{M}_{\text {rec }}^{\text {msr }}$.
Assume now that there is an estimable semimeasure $S \unrhd \mathcal{M}_{\text {rec }}^{\mathrm{msr}}$. We construct a recursive semimeasure $P \unrhd S$ as follows. Choose an initial $\varepsilon>0$ and finitely compute an $\varepsilon$-approximation $\hat{S}$ of $S(x)$. If $\hat{S}>2 \varepsilon$ define $P(x):=\frac{1}{2} \hat{S}$, else halve $\varepsilon$ and repeat the process. Since $S(x)>0$ (otherwise it could not dominate, e.g. $T(x):=\frac{1}{x(x+1)} \in \mathcal{M}_{\text {rec }}^{\text {msr }}$ )
the loop terminates after finite time. So $P$ is recursive. Inserting $\hat{S}=2 P(x)$ and $\varepsilon<\frac{1}{2} \hat{S}=P(x)$ into $\mid S(x)-$ $\hat{S} \mid<\varepsilon$ we get $|S(x)-2 P(x)|<P(x)$, which implies $S(x) \geqslant P(x)$ and $S(x) \leqslant 3 P(x)$. The former implies $\sum_{x} P(x) \leqslant \sum_{x} S(x) \leqslant 1$, i.e. $P$ is a semimeasure. The latter implies $P \geqslant \frac{1}{3} S \unrhd \mathcal{M}_{\text {rec }}^{\mathrm{msr}}$. Hence $P$ is a recursive semimeasure dominating all recursive measures, which contradicts what we have proven in the first half of (iii). Hence the assumption on $S$ was wrong which establishes $\mathcal{M}_{\text {est }}^{\text {semi }} \unrhd \mathcal{M}_{\text {rec }}^{\mathrm{msr}}$.
(iv) From (iii) we know that $\mathcal{M}_{\text {est }}^{\text {semi }} \nsubseteq \mathcal{M}_{\text {est }}^{\text {msr }}$. The proof and hence result remains valid under the halting oracle, i.e. $\mathcal{M}_{H \text {-est }}^{\text {semi }} \notin \mathcal{M}_{H \text {-est }}^{\text {msr }}$. By Lemma 6, the $H$-estimable functions/(semi)measures coincide with the approximable functions/(semi)measures, hence $\mathcal{M}_{\mathrm{appr}}^{\mathrm{semi}} \notin \mathcal{M}_{\mathrm{appr}}^{\mathrm{msr}}$.

Proof (continuous case). The major difference to the discrete case is that one also has to take care that $\rho(x) \stackrel{(>)}{=}$ $\rho(x 0)+\rho(x 1), x \in\{0,1\}^{*}$, is respected. On the other hand, the chunking $I_{n}:=\{0,1\}^{n}$ is more natural here.
(o) $\rho(x):=\sum_{v \in \mathcal{M}} w_{v} v(x)$ with $w_{v}>0$ obviously dominates all $v \in \mathcal{M}$ (with domination constant $w_{v}$ ). With $\sum_{v} w_{v}=1$ and all $v$ being (semi)measures also $\rho$ is a (semi)measure.
(i) See [13, Thm. 4.5.1].
(ii) Let $\xi$ be a universal element in $\mathcal{M}_{\text {enum }}^{\text {semi }}$. We define [19]

$$
\xi_{\text {norm }}\left(x_{1: n}\right):=\prod_{t=1}^{n} \frac{\xi\left(x_{1: t}\right)}{\xi\left(x_{<t} 0\right)+\xi\left(x_{<t} 1\right)} .
$$

By induction one can show that $\xi_{\text {norm }}$ is a measure and that $\xi_{\text {norm }}(x) \geqslant \xi(x) \forall x$, hence $\xi_{\text {norm }} \geqslant \xi \unrhd \mathcal{M}_{\text {enum }}^{\text {semi }}$. As a ratio of enumerable functions, $\xi_{\text {norm }}$ is still approximable, hence $\mathcal{M}_{\text {appr }}^{\mathrm{msr}} \unrhd \mathcal{M}_{\text {enum }}^{\text {semi }}$.
(iii) Analogous to the discrete case we could start by recursively defining $x_{k}^{*}:=\arg \min _{x_{k}} \mu\left(x_{<k}^{*} x_{k}\right)$ for $\mu \in \mathcal{M}_{\text {rec }}^{\text {semi }}$. See [5] for a proof along this line. Simpler is to directly consider $\mu \in \mathcal{M}_{\text {est }}^{\text {semi }}$ and to compute $x_{1: \infty}^{*}$ recursively by computing some $\varepsilon$-approximation $e\left(x_{k} \mid x_{<t}^{*}\right)$ of $\mu\left(x_{k} \mid x_{<t}^{*}\right)$ and define $x_{k}^{*}=\arg \min _{x_{k}} e\left(x_{k} \mid x_{<t}^{*}\right)$, which implies $\mu\left(x_{k}^{*} \mid x_{<t}^{*}\right) \leqslant \frac{1}{2}+\varepsilon$. Finally, we define measure $\rho$ by $\rho\left(x_{1: k}^{*}\right)=1 \forall k$ and $\rho(x)=0$ for all $x$ that are not prefixes of $x_{1: \infty}^{*}$. Hence $\mu\left(x_{1: n}^{*}\right) \leqslant\left(\frac{1}{2}+\varepsilon\right)^{n}=\left(\frac{1}{2}+\varepsilon\right)^{n} \rho\left(x_{1: n}^{*}\right)$, which demonstrates that $\mu$ does not dominate $\rho$ for $\varepsilon<\frac{1}{2}$. Since $\mu \in \mathcal{M}_{\text {est }}^{\text {semi }}$ was arbitrary and $\rho$ is a recursive measure, this implies $\mathcal{M}_{\text {est }}^{\text {semi }} \unrhd \mathcal{M}_{\text {rec }}^{\mathrm{msr}}$.
(iv) Identical to discrete case.

## 7. Posterior convergence

We investigated in detail the computational properties of various mixture distributions $\xi$. A mixture $\xi_{\mathcal{M}}$ multiplicatively dominates all distributions in $\mathcal{M}$. We mentioned that dominance implies posterior convergence. In this section we present in more detail what dominance implies and what not.

Convergence of $\xi\left(x_{t} \mid x_{<t}\right)$ to $\mu\left(x_{t} \mid x_{<t}\right)$ with $\mu$-probability 1 tells us that $\xi\left(x_{t} \mid x_{<t}\right)$ is close to $\mu\left(x_{t} \mid x_{<t}\right)$ for sufficiently large $t$ on "most" sequences $x_{1: \infty}$. It says nothing about the speed of convergence, nor whether convergence is true for any particular sequence (of measure 0 ). Convergence in mean sum defined below is intended to capture the rate of convergence, Martin-Löf randomness is used to capture convergence properties for individual sequences.
Martin-Löf randomness is a very important concept of randomness of individual sequences, which is closely related to Kolmogorov complexity and Solomonoff's universal prior. Levin gave a characterization equivalent to Martin-Löf's original definition [11]:

Theorem 7 (Martin-Löf random sequences). A sequence $x_{1: \infty}$ is $\mu$-Martin-Löf random ( $\mu . M . L$.) iff there is a constant $c$ such that $M\left(x_{1: n}\right) \leqslant c \cdot \mu\left(x_{1: n}\right)$ for all $n$.

An equivalent formulation for estimable $\mu$ is:

$$
\begin{equation*}
x_{1: \infty} \text { is } \mu \text {.M.L.-random } \quad \Leftrightarrow \quad \operatorname{Km}\left(x_{1: n}\right)=-\log \mu\left(x_{1: n}\right)+\mathrm{O}(1) \quad \forall n . \tag{7}
\end{equation*}
$$

Theorem 7 follows from (7) by exponentiation, "using $2^{-K m} \approx M$ " and noting that $M \unrhd \mu$ follows from universality of $M$. Consider the special case of $\mu$ being a fair coin, i.e. $\mu\left(x_{1: n}\right)=2^{-n}$, then $x_{1: \infty}$ is M.L. random iff $\operatorname{Km}\left(x_{1: n}\right)=n+\mathrm{O}(1)$,
i.e. if $x_{1: n}$ is incompressible. For general $\mu,-\log \mu\left(x_{1: n}\right)$ is the length of the Shannon-Fano code of $x_{1: n}$, hence $x_{1: \infty}$ is $\mu$.M.L.-random iff the Shannon-Fano code is optimal.

One can show that a $\mu$.M.L.-random sequence $x_{1: \infty}$ passes all thinkable effective randomness tests, e.g. the law of large numbers, the law of the iterated logarithm, etc. In particular, the set of all $\mu$.M.L.-random sequences has $\mu$-measure 1 . The following generalization is natural when considering general Bayes mixtures $\xi$ as in this work:

Definition $8(\mu / \xi$-random sequences $)$. A sequence $x_{1: \infty}$ is called $\mu / \xi$-random ( $\mu$. $\xi$.r.) iff there is a constant $c$ such that $\xi\left(x_{1: n}\right) \leqslant c \cdot \mu\left(x_{1: n}\right)$ for all $n$.

Typically, $\xi$ is a mixture over some $\mathcal{M}$ as defined in (6), in which case the reverse inequality $\xi(x) \unrhd \mu(x)$ is also true (for all $x$ ). For finite $\mathcal{M}$ or if $\xi \in \mathcal{M}$, the definition of $\mu / \xi$-randomness depends only on $\mathcal{M}$, and not on the specific weights $w_{v}$ used in $\xi$. For $\mathcal{M}=\mathcal{M}_{\text {enum }}^{\text {semi }}, \mu / \xi$-randomness is just $\mu$.M.L.-randomness. The larger $\mathcal{M}$, the more patterns are recognized as nonrandom. Roughly speaking, those regularities characterized by some $v \in \mathcal{M}$ are recognized by $\mu / \xi$-randomness, i.e. for $\mathcal{M} \subset \mathcal{M}_{\text {enum }}^{\text {semi }}$ some $\mu / \xi$-random strings may not be M.L. random. Other randomness concepts, e.g. those by Schnorr, Ko, van Lambalgen, Lutz, Kurtz, von Mises, Wald, and Church (see [22,10,16]), could possibly also be characterized in terms of $\mu / \xi$-randomness for particular choices of $\mathcal{M}$.

A classical (non-random) real-valued sequence $a_{t}$ is defined to converge to $a_{*}$, short $a_{t} \rightarrow a_{*}$ if $\forall \varepsilon \exists t_{0} \forall t \geqslant t_{0}$ : $\left|a_{t}-a_{*}\right|<\varepsilon$. We are interested in convergence properties of random sequences $z_{t}(\omega)$ for $t \rightarrow \infty$ (e.g. $z_{t}(\omega)=$ $\left.\xi\left(\omega_{t} \mid \omega_{<t}\right)-\mu\left(\omega_{t} \mid \omega_{<t}\right)\right)$. We denote $\mu$-expectations by $\mathbf{E}$. The expected value of a function $f: \mathcal{X}^{t} \rightarrow \mathbb{R}$, dependent on $x_{1: t}$, independent of $x_{t+1: \infty}$, and possibly undefined on a set of $\mu$-measure 0 , is $\mathbf{E}[f]=\sum_{x_{1: t} \in \mathcal{X}^{t}}^{\prime} \mu\left(x_{1: t}\right) f\left(x_{1: t}\right)$. The prime denotes that the sum is restricted to $x_{1: t}$ with $\mu\left(x_{1: t}\right) \neq 0$. Similarly we use $\mathbf{P}[.$.$] to denote the \mu$-probability of event [..]. We define four convergence concepts for random sequences.

Definition 9 (Convergence of random sequences). Let $z_{1}(\omega), z_{2}(\omega), \ldots$ be a sequence of real-valued random variables. $z_{t}$ is said to converge for $t \rightarrow \infty$ to (random variable) $z_{*}$
(i) with probability 1 (w.p.1) $: \Leftrightarrow \mathbf{P}\left[\left\{\omega: z_{t} \rightarrow z_{*}\right\}\right]=1$,
(ii) in mean sum (i.m.s.) : $\Leftrightarrow \sum_{t=1}^{\infty} \mathbf{E}\left[\left(z_{t}-z_{*}\right)^{2}\right]<\infty$,
(iii) for every $\mu$-M.-L. random sequence ( $\mu$.M.L.) : $\Leftrightarrow \forall \omega$ : If $\left[\exists c \forall n: M\left(\omega_{1: n}\right) \leqslant c \mu\left(\omega_{1: n}\right)\right]$ then $z_{t}(\omega) \rightarrow z_{*}(\omega)$ for $t \rightarrow \infty$,
(iv) for every $\mu / \xi$-random sequence $\left(\mu . \xi\right.$.r.) : $\Leftrightarrow \forall \omega$ : If $\left[\exists c \forall n: \xi\left(\omega_{1: n}\right) \leqslant c \mu\left(\omega_{1: n}\right)\right]$ then $z_{t}(\omega) \rightarrow z_{*}(\omega)$ for $t \rightarrow \infty$.

In statistics, (i) is the "default" characterization of convergence of random sequences. Convergence i.m.s. (ii) is very strong: it provides a rate of convergence in the sense that the expected number of times $t$ in which $z_{t}$ deviates more than $\varepsilon$ from $z_{*}$ is finite and bounded by $c / \varepsilon^{2}$ and the probability that the number of $\varepsilon$-deviations exceeds $\frac{c}{\varepsilon^{2} \delta}$ is smaller than $\delta$, where $c:=\sum_{t=1}^{\infty} \mathbf{E}\left[\left(z_{t}-z_{*}\right)^{2}\right]$. Nothing can be said for which $t$ these deviations occur. If, additionally, $\left|z_{t}-z_{s}\right|$ were monotone decreasing, then $\left|z_{t}-z_{*}\right|=\mathrm{o}\left(t^{-1 / 2}\right)$ could be concluded. (iii) uses M.-L.'s notion of randomness of individual sequences to define convergence M.L. Since this work deals with general Bayes mixtures $\xi$, we generalized in (iv) the definition of convergence M.L. based on $M$ to convergence $\mu$. $\xi$.r. based on $\xi$ in a natural way. One can show that convergence i.m.s. implies convergence w.p.1. Also convergence M.L. implies convergence w.p.1. Universality of $\xi$ implies the following posterior convergence results:

Theorem 10 (Convergence of $\xi$ to $\mu$ ). Let there be sequences $x_{1} x_{2} \ldots$ over a finite alphabet $\mathcal{X}$ drawn with probability $\mu\left(x_{1: n}\right) \in \mathcal{M}$ for the first $n$ symbols, where $\mu$ is a measure and $\mathcal{M}$ a countable set of (semi)measures. The universal/mixture posterior probability $\xi\left(x_{t} \mid x_{<t}\right)$ of the next symbol $x_{t}$ given $x_{<t}$ is related to the true posterior probability $\mu\left(x_{t} \mid x_{<t}\right)$ in the following way:

$$
\sum_{t=1}^{n} \mathbf{E}\left[\left(\sqrt{\frac{\xi\left(x_{t} \mid x_{<t}\right)}{\mu\left(x_{t} \mid x_{<t}\right)}}-1\right)^{2}\right] \leqslant \sum_{t=1}^{n} \mathbf{E}\left[\sum_{x_{t}^{\prime}}\left(\sqrt{\xi\left(x_{t}^{\prime} \mid x_{<t}\right)}-\sqrt{\mu\left(x_{t}^{\prime} \mid x_{<t}\right)}\right)^{2}\right] \leqslant \ln w_{\mu}^{-1}<\infty
$$

where $w_{\mu}$ is the weight (6) of $\mu$ in $\xi$.

Theorem 10 implies

$$
\sqrt{\xi\left(x_{t}^{\prime} \mid x_{<t}\right)} \rightarrow \sqrt{\mu\left(x_{t}^{\prime} \mid x_{<t}\right)} \quad \text { for any } x_{t}^{\prime} \quad \text { and } \quad \sqrt{\frac{\xi\left(x_{t} \mid x_{<t}\right)}{\mu\left(x_{t} \mid x_{<t}\right)}} \rightarrow 1,
$$

both i.m.s. for $t \rightarrow \infty$.
The latter strengthens the result $\xi\left(x_{t} \mid x_{<t}\right) / \mu\left(x_{t} \mid x_{<t}\right) \rightarrow 1$ w.p. 1 derived by Gács [13, Thm. 5.2.2] in that it also provides the "speed" of convergence.

Note also the subtle difference between the two convergence results. For any sequence $x_{1: \infty}^{\prime}$ (possibly constant and not necessarily $\mu$-random), $\mu\left(x_{t}^{\prime} \mid x_{<t}\right)-\xi\left(x_{t}^{\prime} \mid x_{<t}\right)$ converges to zero w.p. 1 (referring to $x_{1: \infty}$ ), but no statement is possible for $\xi\left(x_{t}^{\prime} \mid x_{<t}\right) / \mu\left(x_{t}^{\prime} \mid x_{<t}\right)$, since lim inf $\mu\left(x_{t}^{\prime} \mid x_{<t}\right)$ could be zero. On the other hand, if we stay on-sequence $\left(x_{1: \infty}^{\prime}=x_{1: \infty}\right)$, we have $\xi\left(x_{t} \mid x_{<t}\right) / \mu\left(x_{t} \mid x_{<t}\right) \rightarrow 1$ w.p. 1 (whether inf $\mu\left(x_{t} \mid x_{<t}\right)$ tends to zero or not does not matter). Indeed, it is easy to give an example where $\xi\left(x_{t}^{\prime} \mid x_{<t}\right) / \mu\left(x_{t}^{\prime} \mid x_{<t}\right)$ diverges. If we choose

$$
\mathcal{M}=\left\{\mu_{1}, \mu_{2}\right\}, \quad \mu \equiv \mu_{1}, \quad \mu_{1}\left(1 \mid x_{<t}\right)=\frac{1}{2} t^{-3} \quad \text { and } \quad \mu_{2}\left(1 \mid x_{<t}\right)=\frac{1}{2} t^{-2}
$$

the contribution of $\mu_{2}$ to $\xi$ causes $\xi$ to fall off like $\mu_{2} \sim t^{-2}$, much slower than $\mu \sim t^{-3}$ causing the quotient to diverge:

$$
\begin{aligned}
\mu_{1}\left(0_{1: n}\right) & =\prod_{t=1}^{n}\left(1-\frac{1}{2} t^{-3}\right) \xrightarrow{n \rightarrow \infty} c_{1}=0.450 \ldots>0 \Rightarrow 0_{1: \infty} \text { is a } \mu \text {-random sequence }, \\
\mu_{2}\left(0_{1: n}\right) & =\prod_{t=1}^{n}\left(1-\frac{1}{2} t^{-2}\right) \xrightarrow{n \rightarrow \infty} c_{2}=0.358 \ldots>0 \Rightarrow \xi\left(0_{1: n}\right) \rightarrow w_{1} c_{1}+w_{2} c_{2}:=c_{\xi}>0, \\
\xi\left(0_{<t} 1\right) & =w_{1} \mu_{1}\left(1 \mid 0_{<t}\right) \mu_{1}\left(0_{<t}\right)+w_{2} \mu_{2}\left(1 \mid 0_{<t}\right) \mu_{2}\left(0_{<t}\right) \rightarrow \frac{1}{2} w_{2} c_{2} t^{-2} \\
& \Rightarrow \xi\left(1 \mid 0_{<t}\right)=\frac{\xi\left(0_{<t}\right)}{\xi\left(0_{<t}\right)} \rightarrow \frac{w_{2} c_{2}}{2 c_{\xi}} t^{-2} \Rightarrow \frac{\xi\left(1 \mid 0_{<t}\right)}{\mu\left(1 \mid 0_{<t}\right)} \rightarrow \frac{w_{2} c_{2}}{c_{\xi}} t \rightarrow \infty \text { diverges. }
\end{aligned}
$$

Proof. For a probability distribution $y_{i} \geqslant 0$ with $\sum_{i} y_{i}=1$ and a semi-distribution $z_{i} \geqslant 0$ with $\sum_{i} z_{i} \leqslant 1$ and $i=$ $\{1, \ldots, N\}$, the Hellinger distance $h(\vec{y}, \vec{z}):=\sum_{i}\left(\sqrt{y_{i}}-\sqrt{z_{i}}\right)^{2}$ is upper bounded by the relative entropy $d(\vec{y}, \vec{z})=$ $\sum_{i} y_{i} \ln \frac{y_{i}}{z_{i}}$ (and $0 \ln \frac{0}{z}:=0$ ). This can be seen as follows: For arbitrary $0 \leqslant y \leqslant 1$ and $0 \leqslant z \leqslant 1$ we define

$$
f(y, z):=y \ln \frac{y}{z}-(\sqrt{y}-\sqrt{z})^{2}+z-y=2 y g(\sqrt{z / y})
$$

with $g(t):=-\ln t+t-1 \geqslant 0$. This shows $f \geqslant 0$, and hence $\sum_{i} f\left(y_{i}, z_{i}\right) \geqslant 0$, which implies

$$
\sum_{i} y_{i} \ln \frac{y_{i}}{z_{i}}-\sum_{i}\left(\sqrt{y_{i}}-\sqrt{z_{i}}\right)^{2} \geqslant \sum_{i} y_{i}-\sum_{i} z_{i} \geqslant 1-1=0 .
$$

The (conditional) $\mu$-expectations of a function $f: \mathcal{X}^{t} \rightarrow \mathbb{R}$ are defined as

$$
\mathbf{E}[f]=\sum_{x_{1: t} \in \mathcal{X}^{t}}^{\prime} \mu\left(x_{1: t}\right) f\left(x_{1: t}\right) \quad \text { and } \quad \mathbf{E}_{t}[f]:=\mathbf{E}\left[f \mid x_{<t}\right]=\sum_{x_{t} \in \mathcal{X}}^{\prime} \mu\left(x_{t} \mid x_{<t}\right) f\left(x_{1: t}\right),
$$

where $\sum^{\prime}$ sums over all $x_{t}$ or $x_{1: t}$ for which $\mu\left(x_{1: t}\right) \neq 0$. If we insert $\mathcal{X}=\{1, \ldots, N\}, N=|\mathcal{X}|, i=x_{t}, y_{i}=\mu_{t}:=$ $\mu\left(x_{t} \mid x_{<t}\right)$, and $z_{i}=\xi_{t}:=\xi\left(x_{t} \mid x_{<t}\right)$ into $h$ and $d$ we get (w.p.1)

$$
h_{t}\left(x_{<t}\right):=\sum_{x_{t}}\left(\sqrt{\mu_{t}}-\sqrt{\xi_{t}}\right)^{2} \leqslant d_{t}\left(x_{<t}\right):=\sum_{x_{t}} \mu_{t} \ln \frac{\mu_{t}}{\xi_{t}}=\mathbf{E}_{t}\left[\ln \frac{\mu_{t}}{\xi_{t}}\right] .
$$

Taking the expectation $\mathbf{E}$ and the sum $\sum_{t=1}^{n}$ we get

$$
\begin{equation*}
\sum_{t=1}^{n} \mathbf{E}\left[d_{t}\left(x_{<t}\right)\right]=\sum_{t=1}^{n} \mathbf{E}\left[\mathbf{E}_{t}\left[\ln \frac{\mu_{t}}{\xi_{t}}\right]\right]=\mathbf{E}\left[\ln \prod_{t=1}^{n} \frac{\mu_{t}}{\xi_{t}}\right]=\mathbf{E}\left[\ln \frac{\mu\left(x_{1: n}\right)}{\xi\left(x_{1: n}\right)}\right] \leqslant \ln w_{\mu}^{-1}, \tag{8}
\end{equation*}
$$

where we have used $\mathbf{E}[\mathbf{E} t[.]]=.\mathbf{E}[.$.$] and exchanged the t$-sum with the expectation $\mathbf{E}$, which transforms to a product inside the logarithm. In the last equality we have used the chain rule for $\mu$ and $\xi$. Using universality $\xi\left(x_{1: n}\right) \geqslant w_{\mu} \mu\left(x_{1: n}\right)$ yields the final inequality. Finally

$$
\mathbf{E}_{t}\left[\left(\sqrt{\frac{\xi_{t}}{\mu_{t}}}-1\right)^{2}\right]=\sum_{x_{t}}^{\prime} \mu_{t}\left(\sqrt{\frac{\xi_{t}}{\mu_{t}}}-1\right)^{2}=\sum_{x_{t}}^{\prime}\left(\sqrt{\xi_{t}}-\sqrt{\mu_{t}}\right)^{2} \leqslant h_{t}\left(x_{<t}\right) \leqslant d_{t}\left(x_{<t}\right)
$$

Taking the expectation $\mathbf{E}$ and the sum $\sum_{t=1}^{n}$ and chaining the result with (8) yields Theorem 10.

## 8. Convergence in M.L. sense

An interesting open question is whether $\xi$ converges to $\mu$ (in difference or ratio) individually for all M.-L. random sequences. Clearly, convergence $\mu$.M.L. may at most fail for a set of sequences with $\mu$-measure zero. A convergence M.L. result would be particularly interesting and natural for Solomonoff's universal prior M, since M.L. randomness can be defined in terms of $M$ (see Theorem 7). Attempts to convert the bounds in Theorem 10 to effective $\mu$.M.L.randomness tests fail, since $M\left(x_{t} \mid x_{<t}\right)$ is not enumerable. The proof of $M / \mu \xrightarrow{\text { M.L. }} 1$ given in [13, Thm. 5.2.2, 20, Thm. $10]$ is incomplete. ${ }^{1}$ The implication " $M\left(x_{1: n}\right) \leqslant c \cdot \mu\left(x_{1: n}\right) \forall n \Rightarrow \lim _{n \rightarrow \infty} M\left(x_{1: n}\right) / \mu\left(x_{1: n}\right)$ exists" has been used, but not proven, and is indeed generally wrong [8]. Theorem 7 only implies $\sup _{n} M\left(x_{1: n}\right) / \mu\left(x_{1: n}\right)<\infty$ for M.L. random sequences $x_{1: \infty}$, and [2, pp. 324-325] implies only that $\lim _{n \rightarrow \infty} M\left(x_{1: n}\right) / \mu\left(x_{1: n}\right)$ exists w.p.1, and not $\mu$.M.L. Vovk [21] shows that for two estimable semimeasures $\mu$ and $\rho$ and $x_{1: \infty}$ being $\mu$ and $\rho$ M.L. random that

$$
\sum_{t=1}^{\infty} \sum_{x_{t}^{\prime}}\left(\sqrt{\mu\left(x_{t}^{\prime} \mid x_{<t}\right)}-\sqrt{\rho\left(x_{t}^{\prime} \mid x_{<t}\right)}\right)^{2}<\infty \quad \text { and } \quad \sum_{t=1}^{\infty}\left(\frac{\rho\left(x_{t} \mid x_{<t}\right)}{\mu\left(x_{t} \mid x_{<t}\right)}-1\right)^{2}<\infty
$$

If $M$ were estimable, then this would imply posterior $M \rightarrow \mu$ and $M / \mu \rightarrow 1$ for every $\mu$.M.L.-random sequence $x_{1: \infty}$, since every sequence is M.M.L. random. Since $M$ is not estimable, Vovk's theorem cannot be applied and it is not obvious how to generalize it. So the question of individual convergence remains open. More generally, one may ask whether $\xi_{\mathcal{M}} \rightarrow \mu$ for every $\mu / \xi$-random sequence. It turns out that this is true for some $\mathcal{M}$, but false for others.

Theorem $11(\mu / \xi$-convergence of $\xi$ to $\mu)$. Let $\mathcal{X}=\{0,1\}$ be binary and $\mathcal{M}_{\Theta}:=\left\{\mu_{\theta}: \mu_{\theta}\left(1 \mid x_{<t}\right)=\theta \forall t, \theta \in \Theta\right\}$ be the set of Bernoulli( $\theta$ ) distributions with parameters $\theta \in \Theta$. Let $\Theta_{D}$ be a countable dense subset of $[0,1]$, e.g. $[0,1] \cap \mathbb{Q}$, and let $\Theta_{G}$ be a countable subset of $[0,1]$ with a gap in the sense that there exist $0<\theta_{0}<\theta_{1}<1$ such that $\left[\theta_{0}, \theta_{1}\right] \cap \Theta_{G}=\left\{\theta_{0}, \theta_{1}\right\}$, e.g. $\Theta_{G}=\left\{\frac{1}{4}, \frac{1}{2}\right\}$ or $\Theta_{G}=\left(\left[0, \frac{1}{4}\right] \cup\left[\frac{1}{2}, 1\right]\right) \cap \mathbb{Q}$. Then
(i) If $x_{1: \infty}$ is $\mu / \xi_{\mathcal{M}_{\Theta_{D}}}$ random with $\mu \in \mathcal{M}_{\Theta_{D}}$, then $\xi_{\mathcal{M}_{\Theta_{D}}}\left(x_{t} \mid x_{<t}\right) \rightarrow \mu\left(x_{t} \mid x_{<t}\right)$,
(ii) There are $\mu \in \mathcal{M}_{\Theta_{G}}$ and $\mu / \xi_{\mathcal{M}_{\theta_{G}}}$ random $x_{1: \infty}$ for which $\xi_{\mathcal{M}_{\Theta_{G}}}\left(x_{t} \mid x_{<t}\right) \nrightarrow \mu\left(x_{t} \mid x_{<t}\right)$.

Our original/main motivation of studying $\mu / \xi$-randomness is the implication of Theorem 11 that $M \xrightarrow{\text { M.L. }} \mu$ cannot be decided from $M$ being a mixture distribution or from the universality property (Theorem 3) alone. Further structural properties of $\mathcal{M}_{\text {enum }}^{\text {semi }}$ have to be employed. For Bernoulli sequences, convergence $\mu . \xi_{\mathcal{M}_{\theta}}$.r. is related to denseness of $\mathcal{M}_{\Theta}$. May be a denseness characterization of $\mathcal{M}_{\text {enum }}^{\text {semi }}$ can solve the question of convergence M.L. of $M$. The property $M \in \mathcal{M}_{\text {enum }}^{\text {semi }}$ is also not sufficient to resolve this question, since there are $\mathcal{M} \ni \xi$ for which $\xi \xrightarrow{\mu \cdot \xi \cdot r} \mu$ and $\mathcal{M} \ni \xi$ for which $\xi \stackrel{\mu}{\mu, \xi \cdot r} \mu$. Theorem 11 can be generalized to i.i.d. sequences over general finite alphabet $\mathcal{X}$.

[^1]The idea to prove (ii) is to construct a sequence $x_{1: \infty}$ that is $\mu_{\theta_{0}} / \xi$-random and $\mu_{\theta_{1}} / \xi$-random for $\theta_{0} \neq \theta_{1}$. This is possible if and only if $\Theta$ contains a gap and $\theta_{0}$ and $\theta_{1}$ are the boundaries of the gap. Obviously $\xi$ cannot converge to $\theta_{0}$ and $\theta_{1}$, thus proving non-convergence. For no $\theta \in[0,1]$ will this $x_{1: \infty}$ be $\mu_{\theta}$ M.L.-random. Finally, the proof of Theorem 11 makes essential use of the mixture representation of $\xi$, as opposed to the proof of Theorem 10 which only needs dominance $\xi \unrhd \mathcal{M}$.
An example for (ii) is $\mathcal{M}=\left\{\mu_{0}, \mu_{1}\right\}, \mu_{0}\left(1 \mid x_{<t}\right)=\mu_{1}\left(0 \mid x_{<t}\right)=\frac{1}{4}, x_{1: \infty}=(01)^{\infty}=01010101 \ldots \Rightarrow \mu_{0}\left(x_{1: 2 n}\right)=$ $\mu_{1}\left(x_{1: 2 n}\right)=\xi\left(x_{1: 2 n}\right)=\left(\frac{1}{4}\right)^{n}\left(\frac{3}{4}\right)^{n} \Rightarrow x_{1: \infty}$ is $\mu_{0} / \xi$-random and $\mu_{1} / \xi$-random, but $\mu_{0}\left(x_{2 n} \mid x_{<2 n}\right)=\frac{1}{4}, \mu_{0}\left(x_{2 n+1} \mid x_{1: 2 n}\right)=$ $\frac{3}{4}, \mu_{1}\left(x_{2 n} \mid x_{<2 n}\right)=\frac{3}{4}, \mu_{1}\left(x_{2 n+1} \mid x_{1: 2 n}\right)=\frac{1}{4}$ and $\xi\left(x_{2 n} \mid x_{<2 n}\right)=\frac{3}{8}, \xi\left(x_{2 n+1} \mid x_{1: 2 n}\right)=\frac{1}{2}$ for $w_{0}=w_{1}=\frac{1}{2} \Rightarrow$ $\xi\left(x_{n} \mid x_{<n}\right) \nrightarrow \mu_{0 / 1}\left(x_{n} \mid x_{<n}\right)$.

Proof. Let $\mathcal{X}=\{0,1\}$ and $\mathcal{M}=\left\{\mu_{\theta}: \theta \in \Theta\right\}$ with countable $\Theta \subset[0,1]$ and $\mu_{\theta}\left(1 \mid x_{1: n}\right)=\theta=1-\mu_{\theta}\left(0 \mid x_{1: n}\right)$, which implies

$$
\mu_{\theta}\left(x_{1: n}\right)=\theta^{n_{1}}(1-\theta)^{n-n 1}, \quad n_{1}:=x_{1}+\cdots+x_{n}, \quad \hat{\theta} \equiv \hat{\theta}_{n}:=\frac{n_{1}}{n}
$$

$\hat{\theta}$ depends on $n$; all other used/defined $\theta$ will be independent of $n$. We assume $\theta . . \in \Theta$, where .. stands for some (possible empty) index, and $\ddot{\theta} \in[0,1]$ (possibly $\neq \Theta$ ), where .. stands for some superscript, i.e. $\mu_{\theta . \text {. }}$ and $w_{\theta \text {. }}$ make sense, whereas $\mu_{\ddot{\theta}}$ and $w_{\ddot{\theta}}$ do not. $\xi$ is defined in the standard way as

$$
\begin{equation*}
\xi\left(x_{1: n}\right)=\sum_{\theta \in \Theta} w_{\theta} \mu_{\theta}\left(x_{1: n}\right) \quad \Rightarrow \quad \xi\left(x_{1: n}\right) \geqslant w_{\theta} \mu_{\theta}\left(x_{1: n}\right), \tag{9}
\end{equation*}
$$

where $\sum_{\theta} w_{\theta}=1$ and $w_{\theta}>0 \forall \theta$. In the following let $\mu=\mu_{\theta_{0}} \in \mathcal{M}$ be the true environment

$$
\begin{equation*}
\omega=x_{1: \infty} \text { is } \mu / \xi \text {-random } \Leftrightarrow \exists_{c_{\omega}}: \xi\left(x_{1: n}\right) \leqslant c_{\omega} \cdot \mu_{\theta_{0}}\left(x_{1: n}\right) \quad \forall n . \tag{10}
\end{equation*}
$$

For binary alphabet it is sufficient to establish whether $\xi\left(1 \mid x_{1: n}\right) \xrightarrow{n \rightarrow \infty} \theta_{0} \equiv \mu\left(1 \mid x_{1: n}\right)$ for $\mu / \xi$-random $x_{1: \infty}$ in order to decide $\xi\left(x_{n} \mid x_{<n}\right) \rightarrow \mu\left(x_{n} \mid x_{<n}\right)$. We need the following posterior representation of $\xi$ :

$$
\begin{equation*}
\xi\left(1 \mid x_{1: n}\right)=\sum_{\theta \in \Theta} w_{n}^{\theta} \mu_{\theta}\left(1 \mid x_{1: n}\right), \quad w_{n}^{\theta}:=w_{\theta} \frac{\mu_{\theta}\left(x_{1: n}\right)}{\xi\left(x_{1: n}\right)} \leqslant \frac{w_{\theta}}{w_{\theta_{0}}} \frac{\mu_{\theta}\left(x_{1: n}\right)}{\mu_{\theta_{0}}\left(x_{1: n}\right)}, \quad \sum_{\theta \in \Theta} w_{n}^{\theta}=1 . \tag{11}
\end{equation*}
$$

The ratio $\mu_{\theta} / \mu_{\theta_{0}}$ can be represented as follows:

$$
\begin{align*}
\frac{\mu_{\theta}\left(x_{1: n}\right)}{\mu_{\theta_{0}}\left(x_{1: n}\right)} & =\frac{\theta^{n 1}(1-\theta)^{n-n_{1}}}{\theta_{0}^{n 1}\left(1-\theta_{0}\right)^{n-n_{1}}}=\left[\left(\frac{\theta}{\theta_{0}}\right)^{\hat{\theta}_{n}}\left(\frac{1-\theta}{1-\theta_{0}}\right)^{1-\hat{\theta}_{n}}\right]^{n} \\
& =\mathrm{e}^{n\left[D\left(\hat{\theta}_{n} \| \theta_{0}\right)-D\left(\hat{\theta}_{n} \| \theta\right)\right]} \quad \text { where } \quad D(\hat{\theta} \| \theta)=\hat{\theta} \ln \frac{\hat{\theta}}{\theta}+(1-\hat{\theta}) \ln \frac{1-\hat{\theta}}{1-\theta} \tag{12}
\end{align*}
$$

is the relative entropy between $\hat{\theta}$ and $\theta$, which is continuous in $\hat{\theta}$ and $\theta$, and is 0 if and only if $\hat{\theta}=\theta$. We also need the following implication for sets $\Omega \subseteq \Theta$ :

$$
\begin{equation*}
\text { If } \quad w_{n}^{\theta} \leqslant w_{\theta} g_{\theta}(n) \xrightarrow{n \rightarrow \infty} 0 \quad \text { and } \quad g_{\theta}(n) \leqslant c \forall \theta \in \Omega, \quad \text { then } \quad \sum_{\theta \in \Omega} w_{n}^{\theta} \mu_{\theta}\left(1 \mid x_{1: n}\right) \leqslant \sum_{\theta \in \Omega} w_{n}^{\theta} \xrightarrow{n \rightarrow \infty} 0, \tag{13}
\end{equation*}
$$

which easily follows from boundedness $\sum_{\theta} w_{n}^{\theta} \leqslant 1$ and $\mu_{\theta} \leqslant 1$ [ 7 , Lem. 5.28ii]. We now prove Theorem 11. We leave the special considerations necessary when $0,1 \in \Theta$ to the reader and assume, henceforth, $0,1 \notin \Theta$.
(i) Let $\Theta$ be a countable dense subset of $(0,1)$ and $x_{1: \infty}$ be $\mu / \xi$-random. Using (9) and (10) in (12) for $\theta \in \Theta$ to be determined later we can bound

$$
\begin{equation*}
\mathrm{e}^{n\left[D\left(\hat{\theta}_{n} \| \theta_{0}\right)-D\left(\hat{\theta}_{n} \| \theta\right)\right]}=\frac{\mu_{\theta}\left(x_{1: n}\right)}{\mu_{\theta_{0}}\left(x_{1: n}\right)} \leqslant \frac{c_{\omega}}{w_{\theta}}=: c<\infty . \tag{14}
\end{equation*}
$$

Let us assume that $\hat{\theta} \equiv \hat{\theta}_{n} \nrightarrow \theta_{0}$. This implies that there exists a cluster point $\tilde{\theta} \neq \theta_{0}$ of sequence $\hat{\theta}_{n}$, i.e. $\hat{\theta}_{n}$ is infinitely often in an $\varepsilon$-neighborhood of $\tilde{\theta}$, e.g. $D\left(\hat{\theta}_{n} \| \tilde{\theta}\right) \leqslant \varepsilon$ for infinitely many $n . \tilde{\theta} \in[0,1]$ may be outside $\Theta$.

Since $\tilde{\theta} \neq \theta_{0}$ this implies that $\hat{\theta}_{n}$ must be "far" away from $\theta_{0}$ infinitely often. For instance, for $\varepsilon=\frac{1}{4}\left(\tilde{\theta}-\theta_{0}\right)^{2}$, using $D\left(\hat{\theta}|\mid \tilde{\theta})+D\left(\hat{\theta}| | \theta_{0}\right) \geqslant\left(\tilde{\theta}-\theta_{0}\right)^{2}\right.$, we get $D\left(\hat{\theta} \| \mid \theta_{0}\right) \geqslant 3 \varepsilon$. We now choose $\theta \in \Theta$ so near to $\tilde{\theta}$ such that $|D(\hat{\theta}|\mid \theta)-D(\hat{\theta}| | \tilde{\theta}) \mid \leqslant \varepsilon$ (here we use denseness of $\Theta$ ). Chaining all inequalities we get $D\left(\hat{\theta} \| \theta_{0}\right)-D(\hat{\theta} \| \theta) \geqslant 3 \varepsilon-\varepsilon-\varepsilon=\varepsilon>0$. This, together with (14) implies $\mathrm{e}^{n \varepsilon} \leqslant c$ for infinitely many $n$ which is impossible. Hence, the assumption $\hat{\theta}_{n} \nrightarrow \theta_{0}$ was wrong.

Now, $\hat{\theta}_{n} \rightarrow \theta_{0}$ implies that for arbitrary $\theta \neq \theta_{0}, \theta \in \Theta$ and for sufficiently large $n$ there exists $\delta_{\theta}>0$ such that $D\left(\hat{\theta}_{n} \| \theta\right) \geqslant 2 \delta_{\theta}$ (since $D\left(\theta_{0} \| \theta\right) \neq 0$ ) and $D\left(\hat{\theta}_{n} \| \theta_{0}\right) \leqslant \delta_{\theta}$. This implies

$$
w_{n}^{\theta} \leqslant \frac{w_{\theta}}{w_{\theta_{0}}} \mathrm{e}^{n\left[D\left(\hat{\theta}_{n} \| \theta_{0}\right)-D\left(\hat{\theta}_{n} \| \theta\right)\right]} \leqslant \frac{w_{\theta}}{w_{\theta_{0}}} \mathrm{e}^{-n \delta_{\theta}} \xrightarrow{n \rightarrow \infty} 0,
$$

where we have used (11) and (12) in the first inequality and the second inequality holds for sufficiently large $n$. Hence $\sum_{\theta \neq \theta_{0}} w_{n}^{\theta} \rightarrow 0$ by (13) and $w_{n}^{\theta_{0}} \rightarrow 1$ by normalization (11), which finally gives

$$
\xi\left(1 \mid x_{1: n}\right)=w_{n}^{\theta_{0}} \mu_{\theta_{0}}\left(1 \mid x_{1: n}\right)+\sum_{\theta \neq \theta_{0}} w_{n}^{\theta} \mu_{\theta}\left(1 \mid x_{1: n}\right) \xrightarrow{n \rightarrow \infty} \mu_{\theta_{0}}\left(1 \mid x_{1: n}\right) .
$$

(ii) We first consider the case $\Theta=\left\{\theta_{0}, \theta_{1}\right\}$ : Let us choose $\bar{\theta}\left(=\ln \left(\frac{1-\theta_{0}}{1-\theta_{1}}\right) / \ln \left(\frac{\theta_{1}}{\theta_{0}} \frac{1-\theta_{0}}{1-\theta_{1}}\right) \neq \Theta\right)$ in the (KL) middle of $\theta_{0}$ and $\theta_{1}$ such that

$$
\begin{equation*}
D\left(\bar{\theta} \| \theta_{0}\right)=D\left(\bar{\theta} \| \theta_{1}\right), \quad 0<\theta_{0}<\bar{\theta}<\theta_{1}<1 \tag{15}
\end{equation*}
$$

and choose $x_{1: \infty}$ such that $\hat{\theta}_{n}:=\frac{n_{1}}{n}$ satisfies $\left|\hat{\theta}_{n}-\bar{\theta}\right| \leqslant \frac{1}{n}\left(\Rightarrow \hat{\theta}_{n} \xrightarrow{n \rightarrow \infty} \bar{\theta}\right)$.
We will show that $x_{1: \infty}$ is $\mu_{\theta_{0}} / \xi$-random and $\mu_{\theta_{1}} / \xi$-random. Obviously no $\xi$ can converge to $\theta_{0}$ and $\theta_{1}$, thus proving $\mu / \xi$-non-convergence. ( $x_{1: \infty}$ is obviously not $\mu_{\theta_{0 / 1}}$ M.L.-random, since the relative frequency $\hat{\theta}_{n} \nrightarrow \theta_{0 / 1} . x_{1: \infty}$ is not even $\mu_{\bar{\theta}}$ M.L.-random, since $\hat{\theta}_{n}$ converges too fast $\left(\sim \frac{1}{n}\right)$. $x_{1: \infty}$ is indeed very regular, whereas $\frac{n_{1}}{n}$ of a truly $\mu_{\bar{\theta}}$ M.L.-random sequence has fluctuations of the order $1 / \sqrt{n}$. The fast convergence is necessary for doubly $\mu / \xi$ randomness. The reason that $x_{1: \infty}$ is $\mu / \xi$-random, but not M.L.-random is that $\mu / \xi$-randomness is a weaker concept than M.L.-randomness for $\mathcal{M} \subset \mathcal{M}_{\text {enum }}^{\text {semi }}$. Only regularities characterized by $v \in \mathcal{M}$ are recognized by $\mu / \xi$-randomness.)

In the following we assume that $n$ is sufficiently large such that $\theta_{0} \leqslant \hat{\theta}_{n} \leqslant \theta_{1}$. We need

$$
\begin{equation*}
\left|D \left(\hat{\theta}|\mid \theta)-D(\bar{\theta} \| \theta)|\leqslant c| \hat{\theta}-\bar{\theta} \mid \quad \forall \theta, \hat{\theta}, \bar{\theta} \in\left[\theta_{0}, \theta_{1}\right]\right.\right. \tag{16}
\end{equation*}
$$

with $c:=\ln \frac{\theta_{1}\left(1-\theta_{0}\right)}{\theta_{0}\left(1-\theta_{1}\right)}<\infty$, which follows for $\hat{\theta} \geqslant \bar{\theta}$ (similarly $\hat{\theta} \leqslant \bar{\theta}$ ) from

$$
D(\hat{\theta} \| \theta)-D(\bar{\theta} \| \theta)=\int_{\bar{\theta}}^{\hat{\theta}}\left[\ln \frac{\theta^{\prime}}{\theta}-\ln \frac{1-\theta^{\prime}}{1-\theta}\right] \mathrm{d} \theta^{\prime} \leqslant \int_{\bar{\theta}}^{\hat{\theta}}\left[\ln \frac{\theta_{1}}{\theta_{0}}-\ln \frac{1-\theta_{1}}{1-\theta_{0}}\right] \mathrm{d} \theta^{\prime}=c \cdot(\hat{\theta}-\bar{\theta}),
$$

where we have increased $\theta^{\prime}$ to $\theta_{1}$ and decreased $\theta$ to $\theta_{0}$ in the inequality. Using (16) in (12) twice we get

$$
\begin{equation*}
\frac{\mu_{\theta_{1}}\left(x_{1: n}\right)}{\mu_{\theta_{0}}\left(x_{1: n}\right)}=\mathrm{e}^{n\left[D\left(\hat{\theta}_{n} \| \theta_{0}\right)-D\left(\hat{\theta}_{n} \| \theta_{1}\right)\right]} \leqslant \mathrm{e}^{n\left[D\left(\bar{\theta} \| \theta_{0}\right)+c\left|\hat{\theta}_{n}-\bar{\theta}\right|-D\left(\bar{\theta}| | \theta_{1}\right)+c\left|\hat{\theta}_{n}-\bar{\theta}\right|\right]} \leqslant \mathrm{e}^{2 c}, \tag{17}
\end{equation*}
$$

where we have used (15) in the last inequality. Now, (17) and (11) lead to

$$
\begin{equation*}
w_{n}^{\theta_{0}}=w_{\theta_{0}} \frac{\mu_{\theta_{0}}\left(x_{1: n}\right)}{\xi\left(x_{1: n}\right)}=\left[1+\frac{w_{\theta_{1}}}{w_{\theta_{0}}} \frac{\mu_{\theta_{1}}\left(x_{1: n}\right)}{\mu_{\theta_{0}}\left(x_{1: n}\right)}\right]^{-1} \geqslant\left[1+\frac{w_{\theta_{1}}}{w_{\theta_{0}}} \mathrm{e}^{2 c}\right]^{-1}=: c_{0}>0, \tag{18}
\end{equation*}
$$

which shows that $x_{1: \infty}$ is $\mu_{\theta_{0}} / \xi$-random by (10). Exchanging $\theta_{0} \leftrightarrow \theta_{1}$ in (17) and (18) we similarly get $w_{n}^{\theta_{1}} \geqslant c_{1}>0$, which implies (using $w_{n}^{\theta_{0}}+w_{n}^{\theta_{1}}=1$ )

$$
\begin{equation*}
\xi\left(1 \mid x_{1: n}\right)=\sum_{\theta \in\left\{\theta_{0}, \theta_{1}\right\}} w_{n}^{\theta} \mu_{\theta}\left(1 \mid x_{1: n}\right)=w_{n}^{\theta_{0}} \cdot \theta_{0}+w_{n}^{\theta_{1}} \cdot \theta_{1} \neq \theta_{0}=\mu_{\theta_{0}}\left(1 \mid x_{1: n}\right) . \tag{19}
\end{equation*}
$$

This shows $\xi\left(1 \mid x_{1: n}\right) \xrightarrow{n \rightarrow \infty} \mu\left(1 \mid x_{1: n}\right)$. One can show that $\xi\left(1 \mid x_{1: n}\right)$ does not only not converge to $\theta_{0}$ (and $\left.\theta_{1}\right)$, but that it does not converge at all. The fast convergence demand $\left|\hat{\theta}_{n}-\bar{\theta}\right| \leqslant \frac{1}{n}$ on $x_{1: \infty}$ can be weakened to $\hat{\theta}_{n} \leqslant \bar{\theta}+\mathrm{O}\left(\frac{1}{n}\right) \forall n$ and $\hat{\theta}_{n} \geqslant \bar{\theta}-\mathrm{O}\left(\frac{1}{n}\right)$ for infinitely many $n$, then $x_{1: \infty}$ is still $\mu_{\theta_{0}} / \xi$-random, and $w_{n}^{\theta_{1}} \geqslant c_{1}^{\prime}>0$ for infinitely many $n$, which is sufficient to prove $\xi \nrightarrow \mu$.

We now consider general $\Theta$ with gap in the sense that there exist $0<\theta_{0}<\theta_{1}<1$ with $\left[\theta_{0}, \theta_{1}\right] \cap \Theta=\left\{\theta_{0}, \theta_{1}\right\}$ : We show that all $\theta \neq \theta_{0}, \theta_{1}$ give asymptotically no contribution to $\xi\left(1 \mid x_{1: n}\right)$, i.e. (19) still applies. Let $\theta \in \Theta \backslash\left\{\theta_{0}, \theta_{1}\right\}$; all other definitions as before. Then $\delta_{\theta}:=D(\bar{\theta} \| \theta)-D\left(\bar{\theta} \| \theta_{0 / 1}\right)>0$, since $\theta$ is farther than $\theta_{0 / 1}$ away from $\bar{\theta}$ $\left(|\theta-\bar{\theta}|>\left|\theta_{0 / 1}-\bar{\theta}\right|\right)$. Similarly to (17) with $\theta$ instead $\theta_{1}$ we get

$$
\frac{\mu_{\theta}\left(x_{1: n}\right)}{\mu_{\theta_{0}}\left(x_{1: n}\right)}=\mathrm{e}^{n\left[D\left(\hat{\theta}_{n} \| \theta_{0}\right)-D\left(\hat{\theta}_{n} \| \theta\right)\right]} \leqslant \mathrm{e}^{2 c} \cdot \mathrm{e}^{n\left[D\left(\bar{\theta} \| \theta_{0}\right)-D(\bar{\theta} \| \theta)\right]}=\mathrm{e}^{2 c} \mathrm{e}^{-n \delta_{\theta}} \xrightarrow{n \rightarrow \infty} 0
$$

Hence $w_{n}^{\theta} \leqslant \frac{w_{\theta}}{w_{\theta_{0}}} \mathrm{e}^{2 c} \mathrm{e}^{-n \delta_{\theta}} \rightarrow 0$ from (11) and $\varepsilon_{n}:=\sum_{\theta \in \Theta \backslash\left\{\theta_{0}, \theta_{1}\right\}} w_{n}^{\theta} \mu_{\theta}\left(1 \mid x_{1: n}\right) \xrightarrow{n \rightarrow \infty} 0$ from (13). Hence $\xi\left(1 \mid x_{1: n}\right)=$ $w_{n}^{\theta_{0}} \cdot \theta_{0}+w_{n}^{\theta_{1}} \cdot \theta_{1}+\varepsilon_{n} \neq \theta_{0}=\mu_{\theta_{0}}\left(1 \mid x_{1: n}\right)$ for sufficiently large $n$, since $\varepsilon_{n} \rightarrow 0, w_{n}^{\theta_{1}} \geqslant c_{1}^{\prime}>0$ and $\theta_{0} \neq \theta_{1}$.

## 9. Conclusions

For a hierarchy of four computability definitions, we completed the classification of the existence of computable (semi)measures dominating all computable (semi)measures. Dominance is an important property of a prior, since it implies rapid convergence of the corresponding posterior with probability one. A strengthening would be convergence for all M.-L. random sequences. This seems natural, since M.L. randomness can be defined in terms of Solomonoff's prior $M$, so there is a close connection. Contrary to what was believed before, the question of posterior convergence $M / \mu \rightarrow 1$ for all M.L. random sequences is still open. Some exciting progress has been made recently in [8], partially answering this question. We introduced a new flexible notion of $\mu / \xi$-randomness which contains M.L. randomness as a special case. Though this notion may have a wider range of application, the main purpose for its introduction was to show that standard proof attempts of $M / \mu \xrightarrow{\text { M.L. }} 1$ based on dominance only must fail. This follows from the derived result that the validity of $\xi / \mu \rightarrow 1$ for $\mu / \xi$-random sequences depends on the Bayes mixture $\xi$.

[^1]:    ${ }^{1}$ The formulation of their theorem is quite misleading in general: "Let $\mu$ be a positive recursive measure. If the length of $y$ is fixed and the length of $x$ grows to infinity, then $M(y \mid x) / \mu(y \mid x) \rightarrow 1$ with $\mu$-probability one. The infinite sequences $\omega$ with prefixes $x$ satisfying the displayed asymptotics are precisely [" $\Rightarrow$ " and " $\Leftarrow$ "] the $\mu$-random sequences." First, for off-sequence $y$ convergence w.p. 1 does not hold ( $x y$ must be demanded to be a prefix of $\omega$ ). Second, the proof of " $\Leftarrow$ " has gaps (see main text). Last, " $\Rightarrow$ " is given without proof and is wrong [8]. Also the assertion in [13, Thm. 5.2.1] that $S_{t}:=\mathbf{E} \sum_{x_{t}^{\prime}}\left(\mu\left(x_{t}^{\prime} \mid x_{<t}\right)-M\left(x_{t}^{\prime} \mid x_{<t}\right)\right)^{2}$ converges to zero faster than $1 / t$ cannot be made, since $S_{t}$ does not decrease monotonically [7, Prob.2.7]. For example, for $a_{t}:=1 / \sqrt{t}$ if $t$ is a cube and 0 otherwise, we have $\sum_{t=1}^{\infty} a_{t}<\infty$, but $a_{t} \neq \mathrm{o}(1 / t)$.
